ABSTRACT

Context. Asteroseismic modelling will play a key role in future space-based missions, such as PLATO, CubeSpec, and *Roman.* Despite remarkable achievements, asteroseismology has revealed significant discrepancies between observations and theoretical predictions of the physics used in stellar models, which have the potential to bias stellar characterisation at the precision level demanded by PLATO. The current modelling strategies largely overlook magnetic activity, assuming that its effects are masked within the parametrisation of the so-called 'surface effects'. Given the presence of activity cycles in multiple solar-like oscillators and activity variations in a significant fraction of *Kepler* observations of main-sequence stars, it is therefore relevant to investigate systematic errors in asteroseismic characterisations caused by our incomplete understanding of magnetic activity.

Aims. Based on 26.5 years of GOLF and BiSON observations, we measured the impact of magnetic activity on the asteroseismic characterisation of the Sun as a star, a reference target for assessing the PLATO mission requirements.

Methods. The GOLF and BiSON observations, which fully cover solar cycles 23 and 24, were divided into yearly overlapping snapshots, each delayed by a quarter of a year. For each snapshot, an advanced asteroseismic characterisation, similar to that to be adopted by the PLATO pipeline, was performed with standard prescriptions for the parametrisation of the surface effects. This allowed us to monitor the apparent temporal evolution of fundamental solar parameters such as mass, radius, and age. The correlation of these parameters with the 10.7 cm radio emission flux, a proxy of the solar activity cycle, was then measured.

Results. The effects of magnetic activity are partially absorbed into the parametrisation of the surface effects when suitable prescriptions are used, and they do not significantly affect the measured solar mass or radius. However, contrary to literature expectations, we find a significant imprint on the age determination, with variations of up to 6.5% between solar minima and maxima. This imprint persists across both BiSON and GOLF datasets.

Conclusions. Considering that the Sun exhibits low levels of activity, our study highlights the looming challenge posed by magnetic activity for future photometry missions, and it prompts a potential reevaluation of the asteroseismic characterisation of the most active *Kepler* targets.

Key words. Sun: activity – Sun: evolution – Sun: fundamental parameters – Sun: helioseismology – Sun: magnetic fields – Sun: oscillations

1. Introduction

Convective motions in the upper layers of solar-type stars excite a broad spectrum of stellar oscillations. Through the study of these oscillations, asteroseismology allows us to probe the internal structure of stars and determine their key parameters, such as mass, radius, and age, with a precision and accuracy that are unmatched by other standard techniques for non-binary stars. Precise and accurate stellar models are crucial for understanding planetary system evolution and unravelling the history of our own galaxy through Galactic archaeology (see e.g. Chaplin & Miglio 2013; García & Ballot 2019). Building on the success of previous missions such as CoRoT (Baglin et al. 2009), *Kepler* (Borucki et al. 2010), K2 (Howell et al. 2014), and TESS (Ricker et al. 2015), asteroseismic modelling will play a key role in the future PLATO (Rauer et al. 2024), CubeSpec (Bowman et al. 2022), and *Roman* (Huber et al. 2023) missions.

Asteroseismology has also highlighted significant discrepancies between observations and theoretical predictions of the physics used in stellar models that can bias stellar characterisation, especially with the precision required by the PLAnetary Transits and Oscillations of stars (PLATO) mission (15% in mass, 1-2% in radius, and 10% in age for a Sun-like star). In particular, the treatment of near-surface layers (e.g. Ball & Gizon 2017; Nsamba et al. 2018; Jørgensen et al. 2020, 2021; Cunha et al. 2021; Bétrisey et al. 2023) and the choice of

^{*} Corresponding author; Jerome.Betrisey@unige.ch

physical ingredients in stellar models (e.g. Buldgen et al. 2019; Farnir et al. 2020; Bétrisey et al. 2022) pose substantial challenges. Modelling inaccuracies in the near-surface layers, known as surface effects, arise notably from the inaccurate treatment of convection in 1D stellar evolutionary models and from neglecting non-adiabatic effects in the oscillation code. As a result, surface effects induce frequency shifts that depend on the frequency, with respect to the eigenfrequencies that are computed with 1D adiabatic oscillation codes (see e.g. Kjeldsen et al. 2008).

However, magnetic stellar activity can also alter the observed frequencies, which complicates the situation further. The current literature on magnetic activity is incomplete, and the distinction between magnetic activity and surface effects remains unclear. From a theoretical standpoint, frequency shifts due to magnetic activity might be caused by structural variations in the sub-surface layers (e.g. Woodard & Noyes 1985; Fossat et al. 1987: Libbrecht & Woodard 1990: Kuhn et al. 1998; Dziembowski & Goode 2005; Basu et al. 2012) and magnetic fields (e.g. Howe et al. 2002; Baldner et al. 2009). In the most recent current modelling strategies, magnetic activity is largely overlooked, and it is assumed that its effects are masked within the parametrisation of the surface effects (see e.g. Pérez Hernández et al. 2019, and references therein). Recent studies have challenged this perspective, however. Pérez Hernández et al. (2019) showed that magnetic activity can have a small but non-negligible impact on the estimation of the stellar mass, radius, age, and helium abundance in two mainsequence stars. Thomas et al. (2021) further showed based on artificial data that magnetic activity might introduce substantial biases in stellar parameter estimation at the precision level required by the PLATO mission. These two studies reported biases up to 10% and 5% for the estimation of the stellar age, respectively, which are comparable to the 10% of precision in age mandated by PLATO. Activity cycles have been detected in many solar-like oscillators (see e.g. Santos et al. 2019a, and references therein) and activity variations were found in a significant fraction of Kepler observations of main-sequence stars (e.g. Santos et al. 2019b, 2021, 2023). It therefore becomes essential to systematically explore and quantify the influence of magnetic activity on the stellar characterisation in preparation for future space-based missions.

To better understand the impact of stellar activity, we decided to examine solar data. The Sun, as our nearest and most extensively studied star, indeed serves as an ideal laboratory for measuring the effects of stellar activity. It is the only star with decades of continuous observations of acoustic oscillations that cover several activity cycles (see Appendix A). Solar observations have revealed that low-degree acoustic frequencies change with the 11-year solar activity cycle (Woodard & Noyes 1985), and this finding has been verified by numerous studies for low and intermediate modes (see e.g. Broomhall & Nakariakov 2015). Additionally, quasi-biennial oscillations have been detected in solar data (see e.g. Mehta et al. 2022), although their physical origin remains unclear (see e.g. Bazilevskaya et al. 2014). Moreover, the imprint of the solar activity cycle has been observed in global seismic observables such as the large separation (Broomhall et al. 2011) and the maximum power frequency (Howe et al. 2020). Magnetic activity therefore directly impacts stellar characterisation when scaling relations are employed (see e.g. Hekker 2020, for a review about scaling relations). We refer to Bétrisey (2024) for a more compete literature review of the impact of magnetic activity on solar acoustic frequencies.

In this Letter, we investigate the influence of magnetic activity on the solar asteroseismic characterisation using an advanced modelling procedure similar to that to be used for PLATO. Our analysis is based on 26.5 years of data from Doppler velocity observations by the Global Oscillations at Low Frequencies (GOLF) instrument and by the Birmingham Solar Oscillations Network (BiSON). In Sect. 2, we detail the datasets and outline the modelling strategy we employed for the characterisation. In Sect. 3, we assess the correlation between various stellar parameters derived from the characterisation and the 10.7 cm radio emission flux, which serves as a proxy of the solar activity cycle. Finally, in Sect. 4, we present our conclusions.

2. Datasets and modelling procedure

Our observational data are composed of high-quality Sun-asa-star measurements of pressure modes across solar cycles 23 and 24. To ensure a robust detection of the correlations with the solar activity cycle, we based our study on two independent datasets: GOLF (Gabriel et al. 1995) and BiSON (Davies et al. 2014; Hale et al. 2016) observations. GOLF, monitoring the Sun from space, and BiSON, observing from the ground, are both sensitive to radial velocity variations, which enables the extraction of high-quality pressure modes. The GOLF observations were divided into 94 yearly overlapping snapshots, each delayed by 91.25 days. Similarly, the BiSON observations were divided into 92 overlapping snapshots. The detailed modelling procedure for acoustic oscillation extraction is provided in Appendix B.

For each snapshot, we characterised the solar parameters using an advanced modelling procedure similar to that to be adopted by the PLATO pipeline. This involves fitting acoustic frequencies and non-seismic constraints (in our case, the effective temperature, metallicity, and luminosity) using the AIMS software (Rendle et al. 2019). We refer to Appendix B for a detailed description of the modelling strategy. The uncertainties of the non-seismic constraints were adjusted to match the data quality of the best Kepler targets. For our study, we used the standard MS subgrid of the Spelaion grid (Bétrisey et al. 2023, hereafter JB23). The combination of this high-resolution grid and the interpolation scheme of AIMS allowed a thorough exploration of the parameter space. We optimised four main free parameters (mass, age, and initial hydrogen, and the helium mass fractions X_0 and Y_0), along with one or two additional free parameters depending on the surface effect prescription considered.

According to the literature, the impact of magnetic activity should be masked within the parametrisation of the surface effects (see e.g. Pérez Hernández et al. 2019, and references therein). However, this has primarily been studied using the Ball & Gizon (2014) surface effect prescription (Howe et al. 2017). Therefore, we also examined the two other main prescriptions from the literature (Kjeldsen et al. 2008; Sonoi et al. 2015). It should be noted that when the frequency shifts due to magnetic activity do not increase monotonically with frequency as they do in the Sun, this indirect treatment of magnetic activity might not be effective (Salabert et al. 2018). Similarly to surface effects, the impact of magnetic activity is stronger on higher-order oscillation frequencies. To investigate whether the characterisation based on mode sets composed of higher-order frequencies is more likely to be affected by magnetic activity, we tested different mode sets by gradually removing the lowest-order modes. For the Sun, instruments such as GOLF and BiSON can detect lower-order frequencies more effectively than the Variability of solar IRradiance and Gravity Oscillations (VIRGO) instrument (Fröhlich et al. 1995) because the photometric background is different. Kepler exhibits a similar behaviour to VIRGO, and

 Table 1. Pearson correlation coefficient between the solar asteroseismic age and the solar activity cycle proxy, the 10.7 cm radio emission flux.

	Cycle 23	Cycle 24	Two cycles			
GOLF						
BG2, $n \ge 12$	0.57 ± 0.12	0.43 ± 0.12	0.50 ± 0.10			
BG2, $n \ge 16$	0.66 ± 0.08	0.61 ± 0.09	0.60 ± 0.05			
BG2, $n \ge 18$	0.14 ± 0.27	0.27 ± 0.19	0.25 ± 0.13			
K1, $n \ge 12$	0.69 ± 0.10	0.32 ± 0.14	0.40 ± 0.02			
K1, <i>n</i> ≥ 16	0.76 ± 0.05	0.35 ± 0.05	0.57 ± 0.09			
$S1, n \ge 12$	MCMC did not converge					
S1, <i>n</i> ≥ 16	MCMC did not converge					
BiSON						
BG2, $n \ge 12$	0.64 ± 0.13	0.64 ± 0.11	0.65 ± 0.12			
BG2, $n \ge 16$	0.66 ± 0.06	0.58 ± 0.07	0.67 ± 0.05			

this is expected to be the case for PLATO as well. Consequently, PLATO observations may potentially be more sensitive to the effects of magnetic activity. The different configurations investigated in our study are summarised in Table 1. We used the same abbreviations as in JB23 for the surface effect prescriptions: BG2 for the two-term Ball & Gizon (2014) prescription, S1 for the one-term Sonoi et al. (2015) prescription, and K1 for the one-term Kjeldsen et al. (2008) prescription. As discussed in JB23 for example, the two-term variants of the S1 and K1 prescriptions are not suitable for asteroseismic targets due to a non-linear free coefficient that destabilises the minimisation procedure. This prevents successful convergence for most cases outside of solar conditions.

3. Imprint of the magnetic activity cycle

As a well-established proxy for solar activity (see e.g. Tapping 2013, and references therein), we used the 10.7 cm radio emission flux¹. The correlation between the solar parameters and the magnetic activity cycle was then evaluated by computing the Pearson correlation coefficient \mathcal{R} (Pearson 1895) between the solar parameters and the 10.7 cm radio emission flux. We refer to Appendix C for a detailed description of the evaluation procedure of the Pearson coefficient.

To maintain conciseness, we highlight the most notable findings here and provide a comprehensive table of all the correlations in Appendix C. The results using the BG2 surface effect prescription are particularly relevant in the framework of the PLATO mission because this prescription is widely adopted by the community and is considered to be most reliable (see e.g. JB23, and references therein). As illustrated in Fig. 1, the activity cycle clearly affects the two free parameters of the BG2 prescription and the estimated stellar age in both the GOLF and BiSON datasets. No imprint is found in the estimated solar mass, radius, and initial chemical composition. While the cycle effect on the surface prescription parameters indicates a partial absorption of activity effects, it is insufficient to prevent an impact on stellar age, contrary to literature expectations. Table 2 shows the age differences between solar minima and maxima of cycles 23 and 24. For cycle 23, we find variations of 5.8% and 6.5% compared with the asteroseismic mean of the corresponding cycle in the GOLF and BiSON datasets, respectively, which is slightly reduced by 0.4% and 0.9% when low-order frequencies are included. For the less active cycle 24, a smaller variation of 4.7%

is observed, as expected for lower activity levels. Nonetheless, these age variations are very significant compared to the 10% age precision required by PLATO. Additionally, for the mode set with radial orders above n = 18, the minimisation is numerically less stable, which leads to larger uncertainties that mask the activity cycle imprint.

By comparing our results with those of Howe et al. (2017), who demonstrated that the effect of magnetic activity can be removed by filtering surface effects if the surface effects prescription parameters are the only free parameters, we note a key difference. We employed an advanced modelling procedure similar to what will be used in the PLATO pipeline, which optimises additional parameters such as stellar mass and age and the initial chemical composition. It is therefore expected that the magnetic activity affects other parameters than the free parameters of the surface effect prescription. Specifically, for the BG2 prescription, only the stellar age is affected, but not the mass, radius, or initial chemical composition. On one hand, this might be due to the intrinsic nature of age in stellar models. The information contained in the oscillation frequencies provides a constraint on the stellar structure. Seismic data can therefore directly constrain the stellar mass, radius, and initial composition. The stellar age, however, is associated with the stellar structure. It is thus constrained by the seismic data in a more indirect way, and consequently, it is more sensitive to modelling inaccuracies. On the other hand, this might be due to the treatment of the stellar age during the interpolation process in AIMS. Further investigation with other minimisation softwares (e.g. BASTA; Aguirre Børsen-Koch et al. 2022) would be relevant to clarify this aspect. Additionally, we also observe a constant age bias of about 300 Myr, which is due to inaccuracies in the surface effect prescription and to a lesser extent to the physical ingredients used in our models.

When the BG2 prescription is used, the activity cycle also leaves a weak imprint on solar parameters such as the large separation, mean density, effective temperature, and absolute luminosity, with Pearson correlation coefficients ranging from 0.3 to 0.5 (see Table C.1 and Fig. C.1). This observation was confirmed by smoothing the data with a Savitzky-Golay filter (Savitzky & Golay 1964) and by visually assessing that two distinct peaks corresponding to the cycle maxima can be identified. These parameters are not free variables in our minimisation process. Thus, the observed imprint is primarily an indirect consequence of the effect on the optimised variables, particularly the stellar age. Notably, the weak imprint on the large separation has also been described in the literature, where this impact has been documented for large separation values that were directly derived from observed solar frequencies (Broomhall et al. 2011).

When we apply the K1 surface effect prescription, the imprint of the magnetic activity cycle on the asteroseismic characterisation remains evident. However, in this case, the free parameter of the K1 prescription shows no correlation with the activity proxy. This suggests that the K1 correction cannot partially account for magnetic activity in the same way the BG2 prescription can. The K1 prescription is known to have limitations at high frequencies (see e.g. JB23, and references therein), which are most strongly affected by magnetic activity. This makes it difficult to estimate this parameter and to decorrelate it from magnetic activity. Similar to the results with the BG2 prescription, the age variations are significant and reach about 6% between solar minima and maxima. Several non-optimised variables show low but non-negligible Pearson coefficients between 0.3 and 0.4 (see Table C.1). However, the data smoothed with the Savitzky-Golay filter show no clear excesses at the solar maxima, which prevents us from conclusively identifying an imprint

Fig. 1. Imprint of the magnetic activity cycle on the asteroseismic characterisation of the Sun. Two different datasets, plotted in blue $(n \ge 12)$ and orange $(n \ge 16)$, were investigated. The black line shows the 10.7 cm radio emission flux, rescaled for illustration purposes. It serves as a proxy of the solar activity cycle. Upper panels: Temporal evolution of the asteroseismic age. Lower panels: Temporal evolution of the free parameters of the two surface effect prescriptions that were investigated. From left to right: Impact of magnetic activity based on BiSON observations and using the BG2 surface effect prescription, the GOLF observations and the BG2 prescription, and the GOLF observations and the K1 prescription.

Table 2. Age variation between solar minima and maxima in cycles 23and 24.

	Cycle	e 23	Cycle 24		
	Absolute	% Age	Absolute	% Age	
GOLF					
BG2, $n \ge 12$	257 Myr	5.4%	197 Myr	4.1%	
BG2, $n \ge 16$	281 Myr	5.8%	227 Myr	4.7%	
K1, $n \ge 12$	264 Myr	5.3%	299 Myr	6.0%	
K1, $n \ge 16$	302 Myr	6.1%	247 Myr	5.0%	
BiSON					
BG2, $n \ge 12$	261 Myr	5.4%	168 Myr	3.5%	
BG2, $n \ge 16$	319 Myr	6.5%	228 Myr	4.7%	

Notes. The left column represents the absolute variation, and the right column compares the absolute variation with the mean asteroseismic age of the corresponding cycle.

of magnetic activity in these variables (see Appendix C). This does not imply that magnetic activity is negligible, but rather that its impact is global, similar to a defect in physical ingredients. It also suggests that the statistical uncertainty of the modelling procedure should be adjusted to account for this. Further investigation would be necessary to determine an appropriate quantitative correction. Nonetheless, because the K1 prescription is not reliable, efforts like this may not be justified.

The S1 prescription produces a bimodal distribution of the free parameter of the surface effect prescription in more than

half of the minimisations. Knowing the expected values for the Sun, we could have discarded the unphysical solution, but this would introduce a bias that is inconsistent with the philosophy of our study. Consequently, we discarded the minimisations with bimodal distributions, which left us with too few data points to meaningfully compute the Pearson coefficient.

4. Conclusions

We studied the impact of the magnetic activity cycle on the asteroseismic characterisation of the Sun as a star based on 26.5 years of GOLF and BiSON Doppler velocity observations. In Sect. 2, we described the observational datasets of the oscillation frequencies and the modelling approach, which is similar to the approach that will be used for PLATO. The correlation of the solar parameters with the 10.7 cm radio emission flux, a proxy for the solar activity cycle, was then investigated in Sect. 3.

Our research has identified a clear impact of the solar magnetic activity cycle on the asteroseismic characterisation of the Sun that notably affects the estimated solar age. This impact was evident in two independent datasets, GOLF and BiSON, and persisted even when the surface effect prescription was modified. Consistently with literature predictions (Howe et al. 2017), the cycle affects the two free parameters of the Ball & Gizon (2014) surface effect prescription. While these parameters can therefore partially mitigate the effects of magnetic activity, they do not completely prevent its imprint on the solar parameters, contrary to previous expectations. Specifically, we found that the estimated solar age varies by about 6.2% on average between solar minima and maxima. This is a substantial difference considering

the 10% age precision required by the PLATO mission for a Sunlike star. Less pronounced variations of about 5.4% and 4.7% on average are observed when low-order modes are included in the mode set or when the cycle is less active, respectively. Using the Ball & Gizon (2014) prescription, we also found a small imprint on the large separation, which is consistent with results reported in the literature (Broomhall et al. 2011), and an effect on the mean density, the effective temperature, and the absolute luminosity. Furthermore, the Kjeldsen et al. (2008) prescription proved to be unable to account for magnetic activity.

For future photometry missions such as PLATO, our study suggests that magnetic activity could present a substantial challenge. While Doppler velocity observations of the Sun as a star by GOLF and BiSON deliver a higher data quality than what is anticipated for the PLATO mission, it is important to note that the Sun is not particularly active (e.g. Reinhold et al. 2020; Santos et al. 2023). In contrast, PLATO is expected to observe many more active stars, but with a lower data quality, which will result in fewer detectable acoustic oscillations. Furthermore, these observations will likely span only a portion of the activity cycle (Breton et al. 2024), and the time series may be insufficiently long to average out the effects of magnetic activity over one or several full cycles. Stellar characterisations may thus be influenced by the phase of the activity cycle, which will lead to potential biases when the observations coincide with cycle extrema. Our study also raises questions about the necessity of reevaluating the asteroseismic characterisation of the most active targets observed by Kepler. This is an important endeavour because most methods for characterising planetary systems rely on the stellar characterisation. Thus, it is imperative to provide robust stellar parameters that consistently account for magnetic activity. In future studies, we will explore these issues further and investigate whether it is possible to mitigate the influence of magnetic activity using standard techniques that are employed to damp surface effects (e.g. Bétrisey et al. 2023). Additionally, it would be worthwhile to examine the impact of magnetic activity on seismic inversion techniques, which also implicitly include magnetic activity within the parametrisation of the surface effects (see e.g. Pijpers 2006; Bétrisey & Buldgen 2022; Buldgen et al. 2022; Bétrisey et al. 2023, 2024).

Appendix A: Solar observational context

Since the 1980s, global networks of ground-based telescopes, such as Interface Region Imaging Spectrograph (IRIS; Fossat 1988), Birmingham Solar Oscillations Network (BiSON; Davies et al. 2014; Hale et al. 2016), Global Oscillations Network Group (GONG; Harvey et al. 1996), and Stellar Observations Network Group (SONG; Grundahl et al. 2006) have been monitoring these oscillations at high cadence and high temporal resolution. For the SONG network, it should be noted that the solar component of the network is called Solar-SONG (see e.g. Breton et al. 2022b, and references therein). Additionally, space-based observations have been made since the mid-1990s by the Variability of solar IRradiance and Gravity Oscillations/Sun PhotoMeters (VIRGO/SPM; Fröhlich et al. 1995), Michelson Doppler Imager (MDI; Scherrer et al. 1995), and Global Oscillations at Low Frequencies (GOLF; Gabriel et al. 1995) instruments on board of the Solar and Heliospheric Observatory (SoHO; Domingo et al. 1995). Since the early 2010s, the Sun is also monitored by the Helioseismic and Magnetic Imager (HMI; Scherrer et al. 2012) on board of the Solar Dynamics Observatory (SDO; Pesnell et al. 2012). This unique dataset provides an excellent opportunity to study the effects of stellar activity, with high-quality acoustic oscillation data being collected continuously for over 30 years, and fully covering solar cycles 23 and 24.

Appendix B: Detailed modelling procedure

The GOLF observations were divided into 94 yearly overlapping snapshots, each delayed by 91.25 days, starting from April 11, 1996, and concluding on July 6, 2020. The acoustic frequency of the p modes in GOLF yearly time series were extracted with the Markov Chain Monte Carlo (MCMC) asteroseismic module APOLLINAIRE (Breton et al. 2022a,b) by analysing the time series power spectral density (PSD) with the following strategy. After removing the background, p modes were fitted by pair $\ell = 0, 2$ and 1, 3, considering an asymmetric Lorentzian profile. Mode height, width, and rotational splitting was fitted independently for each mode, while asymmetry parameter was taken to be common for both modes of a given pair. Power leakage from intermediate-degree $\ell = 4, 5$ was accounted for. The MCMC sampling procedure used the EMCEE (Foreman-Mackey et al. 2013) ensemble sampler. Chains were sampled using 500 walkers and 1000 steps, with the 400 first steps discarded as burnt-in.

Similarly, the BiSON observations were divided into 92 overlapping snapshots, beginning on December 30, 1993, and ending on September 23, 2016. It should be noted that the BiSON time series are publicly available at the BiSON Open Data Portal². The acoustic oscillation frequencies were then extracted using the fitting procedure described in Fletcher et al. (2009).

For each snapshot, the fundamental solar parameters (e.g. mass, radius, age, etc. See Table C.1 for the complete list) were determined using an advanced 'à la PLATO' modelling procedure. To this end, the acoustic frequencies and non-seismic constraints (in our case, the spectroscopic constraints: effective temperature, metallicity, and luminosity) were fitted using the AIMS software (Rendle et al. 2019). As non-seismic constraints, we adopted $T_{\text{eff}} = 5772 \pm 85$ K (Prša et al. 2016), [Fe/H] = 0.00 ± 0.10 , and $L = 1.00 \pm 0.03 L_{\odot}$. The uncertainties of the non-seismic constraints were adjusted to match the data

quality of the best Kepler targets. AIMS, which is an MCMCbased algorithm, is based on the EMCEE package and employs a Bayesian approach to provide posterior probability distributions of the optimised stellar parameters. AIMS also incorporates an interpolation scheme to sample between grid points. We used the standard MS subgrid of the Spelaion grid from Bétrisey et al. (2023). The combination of this high-resolution grid and the interpolation scheme allows for thorough exploration of the parameter space. Four main free parameters (mass, age, and initial hydrogen and helium mass fractions X_0 and Y_0) were optimised, along with one or two additional free parameters depending on the surface effect prescription considered (one for the K1 and S1 surface effect prescriptions and two for the BG2 prescription). Uniform 'uninformative' priors were applied to the estimated stellar parameters, except for the stellar age, for which we employed a uniform distribution in the interval [0, 13.8] Gyr, and likelihoods were calculated under the assumption that the true observational values were perturbed by normally distributed random noise.

Appendix C: Detailed evaluation procedure of the Pearson coefficient

To evaluate the correlation between solar parameters and the magnetic activity cycle, we computed the Pearson correlation coefficient \mathcal{R} (Pearson 1895) using the 10.7 cm radio emission flux, a well-established proxy for solar activity (see e.g. Tapping 2013, and references therein). The 10.7 cm flux data, which is recorded daily in Canada since 1947 and nowadays even includes three measurements per day³, was smoothed to a monthly average. Since the GOLF and BiSON data points do not exactly match the dates of the monthly flux, we linearly interpolated the flux values to ensure consistent calculation of the Pearson coefficient. Additionally, due to the construction of the GOLF and BiSON acoustic oscillation datasets, where data points are correlated over four consecutive points, we created uncorrelated datasets by selecting one data point out of every four. This process resulted in four subsets of the data. For each subset, we calculated the Pearson correlation coefficient. The final Pearson coefficient reported in the tables and figures of this article is the mean of the coefficients from these four subsets. The standard deviation of these coefficients provides an uncertainty measure, reflecting data sensitivity and the confidence level in the estimated Pearson coefficient. It is worth noting that ignoring the correlations in the construction of GOLF and BiSON acoustic oscillation datasets yields similar Pearson coefficients. This similarity is expected, as the construction of these datasets only introduces minor correlations. We provide in Table C.1 the Pearson correlation coefficient between the solar parameters and the 10.7 cm radio emission flux for the different configurations that were investigated in our study.

In Fig. C.1, we show the imprint of magnetic activity cycle on the large separation, mean density, effective temperature, and absolute luminosity using the Ball & Gizon (2014) surface effect prescription, and on the solar mass and radius using the Kjeldsen et al. (2008) prescription. For the imprints with Ball & Gizon (2014) prescription, we smoothed the data with a Savitzky-Golay filter, and confirmed visually that we can clearly identify two distinct peaks corresponding to the cycle maxima. For the Kjeldsen et al. (2008) prescription, we did not find a clear imprint of the cycle by visually inspecting the smoothed data.
